

**UNIVERSAL MICROPHONE FOR SECURE RADIO COMMUNICATION**

**Field of the Invention**

The present invention relates to wireless communication systems, and more specifically, to a method and apparatus for ensuring secure communications between wireless radios.

**Background of the Invention**

Ensuring security in wireless communications has become a growing concern in recent times. Two way wireless communication is used extensively today by a wide variety of users. Police personnel, fire personnel, military personnel, commercial organizations, and ordinary citizens all often utilize two-way radios for communication. Traditionally, such communications were not secure, i.e., anyone with a radio or scanner on the communication frequency could receive and understand the communications. In today's environment, however, a much greater need exists for secure communications in areas where unsecure transmissions were previously sufficient.

In the past, secure transmission systems in the past generally were limited to systems involving high levels of national security. To achieve secure transmissions, encryption techniques are used in high end systems. These techniques involve scrambling a signal (either digital or analog) upon transmission, and then unscrambling the signal upon reception.

The need to add encryption to everyday systems, however, presents a new set of concerns. Currently, in order to make communications secure, two options are available. First, an entirely new system can be installed that contains encryption technology built into each radio, similar to the high end systems used previously in applications involving national

security. The problem, however, is that this approach requires replacing all of the existing hardware currently being used. All existing systems and radios would become obsolete. Because of this limitation, this solution is extremely expensive and cost prohibitive in many cases.

A second, less commonly used option is to install a new component in existing radios to provide encryption. This approach also has significant limitations. Any currently existing encryption components have been designed for specific brands and models of radios. Thus, this retrofit approach is limited in the types of radios to which it can be applied. Furthermore, this approach is costly in that even after the encryption components have been purchased, each radio must be disassembled, the encryption component installed, and the radio reassembled. As a result, this technique has limited practical application.

What is desired is to a system to provide secure transmissions in environments that were traditionally not secure. It is further desired to create secure transmissions in a cost effective manner, using existing radio equipment. This invention fulfills these desires, among others.

### **Summary of the Invention**

The present invention provides a system, method, and apparatus for achieving secure wireless communications. The present invention allows for security to be obtained using existing wireless radios operating on existing communication systems. In accordance with the present invention, an encryption function is incorporated into a microphone unit capable of operating with existing radio equipment. The microphone unit in accordance with the present invention encrypts the signal created from the user's voice and provides it to a radio in the same signal format that the radio would normally receive un-encrypted voice signals. In

this manner, encryption can be provided using existing radios through existing microphone inputs, thus eliminating the need for costly new systems or costly modifications to existing systems.

In a preferred embodiment, the microphone for receiving a voice signal, an analog to digital converter for creating a digital signal from the voice signal, a voice coding device for creating a voice coded signal from the digital signal, encryption means for encrypting the voice coded signal, and a modulator for generating a transmittable signal that can be supplied to a radio via the microphone input.

Additionally, the microphone unit is capable of performing the steps in reverse upon receiving an encrypted signal. The received signal output from the radio is demodulated, un-encrypted, voice decoded, converted from a digital voice signal to an analog voice signal, and output via a speaker which is preferably built into the microphone unit.

### **Brief Description of the Drawings**

Figure 1 is a diagram illustrating an exemplary environment of a two way radios in use.

Figure 2a is a block diagram illustrating the various components of a microphone unit used for transmitting secure communications in accordance with the present invention.

Figure 2b is a flow diagram illustrating the method of creating secure communications in accordance with the present invention.

Figure 3a is a block diagram illustrating the various components of a microphone unit used for receiving secure communications in accordance with the present invention.

Figure 3b is a flow diagram illustrating the method of receiving secure communications in accordance with the present invention.

### **Detailed Description of the Invention**

Figure 1 illustrates an exemplary environment in which a microphone unit in accordance with the present invention can operate. A two-way radio is shown in one of the more common configurations, that is, configured for use by public safety personnel (e.g., police officers, fire personnel). A lapel or shoulder mounted microphone unit 12 is worn on the shoulder of the user. The microphone unit 12 is connect via a cable 14 to the main radio unit 19, which is typically worn on the belt of the user. The main radio unit 19 commonly used by police personnel is a two way radio operating on the UHF band. It is, however, understood that the present invention can be used in conjunction with many types of radios and is not limited to the radio type in the exemplary embodiment.

The microphone unit 12 shown on the officer's shoulder is typically a push to talk (PTT) type unit. A PTT button 16 resides on the microphone unit 12 which the officer depresses in order to activate the microphone in a transmit mode. When the PTT button 16 is not depressed, the microphone unit resides in a receiving mode, whereby incoming communications are broadcast via a speaker 18 contained in the microphone unit 12.

The shoulder worn microphone unit 12 is connected to the main radio unit 19 via a cable 17. The main radio unit 19 can be any type of two way radio unit capable of receiving a microphone input.

The microphone unit 12 in accordance with the present invention shall now be described in detail with reference to Figures 2a, 2b, 3a, and 3b. In Figures 2a and 3a, block diagrams are used to illustrate the various components of an exemplary microphone unit 12 that can be utilized to implement the inventive techniques in accordance with the present invention. Figure 2a illustrates the components used to transmit an encrypted signal, while Figure 3a illustrates the components used to receive an encrypted signal. It should, however,

be understood that, in a preferred embodiment, certain components can be used for both processes. For clarity, separate components are shown in Figures 2a and 3a.

Figure 2b and 3b are flow charts illustrating the two distinct processes performed by a microphone unit in accordance with the present invention. Figure 3a depicts the steps performed on a voice input during the outgoing, or transmission, phase. Figure 3b depicts the steps performed on a signal received from an analog radio during the incoming, or reception, phase.

Referring to Figure 2a and 2b, the transmission phase performed by the microphone unit 12 in accordance with the present invention begins with the user speaking into the microphone unit 12 (step 22). The microphone unit 12 includes a microphone 21. The microphone 21 is used to receive the voice signal from the user. The microphone 21 comprises any standard, commercially available microphone, of which many are well known in the art.

The user input is converted by the microphone 22 from an audible voice signal into a analog voice signal, which is output from the microphone 22. The analog voice signal is then amplified by an amplifier circuit 23 (step 24). Amplification of an analog signal is a well known process that is accomplished using any number of amplification circuits. The amplified analog voice signal is next converted to a digital voice signal (step 26). The conversion from an analog to a digital signal is accomplished using an analog to digital (A/D) converter 25. Standard A/D converters exist which convert analog signals into digital signals. A/D converters are widely available and well known in the art.

Once the input signal has been converted into a digital voice signal, it is processed using a vocoder 27 to transform the digital voice signal into a voice coded digitized voice signal (step 28). Vocoder devices perform a process known as voice coding whereby

digitized voice signals are compressed into lower data rate signals representative of the voice input. Typical digital voice signals require between 64 kilobits/second and 128 kilobits/second. These relatively high data rates, however, are not conducive to efficient digital transmission. Vcoders use a series of digital filters that model the human vocal tract in order to create digital representations of digital voice signals at a significantly lower data rate. For example, typical vocoder outputs require only between 2.4 kilobits/second and 4.8 kilobits/second. In a preferred embodiment, a multiband exciter vocoder is used, such as the AMBE+ advanced multiband exciter vocoder licensed by Digital Voice Systems, Inc. of Westford, MA.

The vocoded signal output by the vocoder 27 is encrypted (step 30). Many types of encryption standards exist. Advanced Encryption Standard (AES) is widely used currently in public safety applications. Thus, in a preferred embodiment, AES encryption is employed. However, it is understood that other known encryptions standards (e.g. DES, Triple DES) or any future developed encryption standards could also be used. In a preferred embodiment, the encryption is performed using software programmed into an encryption module 29 which applies an encryption algorithm to the vocoded signal. The encryption module on which the software operates comprises a digital processors such as, but not limited to, a digital signal processor, a micro processor, a programmed general purpose computer, etc. It also is possible that part or all of the functions of the encryption module may be implemented by analog circuitry.

One problem encountered in encrypted radio systems is that once a unit with the encryption capabilities is lost or stolen, the security of the system is compromised. For example, should an individual obtain a microphone unit in accordance with the present invention, he or she would be able to intercept and understand communications that were

intended to be secure. Thus, it is important to be able to alter the encryption code or "key" in order to ensure that unauthorized units that might have been lost or stolen are no longer able to understand the communications being sent on the system. By using a software "key" stored in a memory 31 within the encryption module 29, it is possible to easily and efficiently change the encryption "key" without requiring the units to be removed from the field to do so. For example, the microphone unit in accordance with the present invention can be equipped with a keypad through which the user can manually reprogram the "key" by entering a new "key" that has been provided to all authorized users. Alternatively, the microphone units could be automatically reprogrammed by broadcasting a new "key" from a base station within the system. Reprogramming the "key" in this manner is fully disclosed in co-pending patent applications entitled Secure Group Secret Distribution (serial no. 10/280,354) and Secure Encryption Key Distribution (serial no. 10/228,747), which are incorporated herein by reference. An example of reprogramming the "key" in this manner is to instruct authorized recipients of the new key to tune to a particular channel at a particular time to receive the new "key" transmission, while the users of the unauthorized units would not know where or when to tune and thus would not receive the new "key."

Once the vocoded voice signal has been encrypted, it is modulated (step 32) onto a carrier signal to create an analog output that can be supplied to a standard analog radio. The analog output from the microphone unit 12 is the same type of signal normally receive from a prior art microphone by the analog radio. Well known modulation circuitry, preferably embodied in a modulator integrated circuit 33, is used to perform the modulation process. The modulated output signal can now be supplied to any standard analog radio (step 34) via the microphone input jack standard on most radios, or alternatively, by hardwiring the microphone unit 12 in accordance with the present invention in place of the microphone of

the existing radio. In either case, minimal or no modifications are necessary to use existing radios to send encrypted transmissions.

In order to complete the communication cycle, the encrypted transmission must be received by a user operating a radio with the ability to decrypt the transmitted signal. This process can be performed by any standard analog radio operating in conjunction with a microphone unit in accordance with the present invention.

Referring to Figures 3a and 3b, the reception phase of a communication is illustrated. The encrypted signal is received as an analog radio signal by a standard analog radio (step 36). This encrypted signal is output from the radio in the same manner that the radio would normally output an unencrypted signal to a speaker unit (e.g., the small speaker contained in a prior art microphone unit worn on the shoulder of a police officer in the configuration as illustrated in Figure 1). The encrypted analog signal is received by the microphone unit 12 and demodulated (step 38) using well known demodulation circuitry, preferably embodied in an integrated circuit 37. The demodulation process removes the encrypted digital signal from the analog carrier signal.

Once the signal has been demodulated, the resulting signal comprises an encrypted digital signal, or an encrypted stream of bits. This encrypted bit stream needs to be decrypted. The decryption process (step 40) is performed on the signal by the decryption module 39, preferably comprising software stored within the microphone unit 12. A decryption algorithm corresponding to the selection encryption standard (e.g., DES, Triple DES, AES, etc.) is applied to the bit stream to remove the encryption, using a security "key" maintained in memory 41 contained within the decryption module 39. The resulting signal is a voice coded, or vocoded, signal representative of vocoded input signal prior to encryption and transmission.

The vocoded signal is applied to a voice decoder 43, preferably contained in the same vocoder chip used for signal compression during the transmission stage, for expansion into a digital signal representative of the digital voice signal created by the input microphone unit (step 42).

At this point, the digital signal can be converted to an analog signal using a digital to analog (D/A) converter 45 (step 44). The resulting analog signal is a voice signal, which is then amplified (step 46) using an amplifier circuit 47 and supplied to a speaker 49 for output as an audible signal to the user (step 48).

By using microphone units in accordance with the present invention, encryption can be added to standard analog radio systems. This eliminates the need for replacing existing radios with new encryption enabled radios or for retrofitting existing radios by installing encryption hardware into the radio unit. Only the microphone unit needs to be replaced. In addition, "end to end" encryption is provided by the present invention. This means the signal remains encrypted, and thus protected from unauthorized interception, from the point of transmission by a first user to the point of reception by a second user. Often radio systems contain several intermediary stages between the first user transmitting a signal and the second user receiving the signal. For instance, the signal may be relayed by a base station or one or more mobile repeater units operating in the system. These intermediary units allow the operating range of a radio system to be extended far beyond the range of any individual radio. Because the encrypted signal transmitted by a radio operating in conjunction with a microphone in accordance with the present invention appears to the intermediary units as a standard analog radio signal, the intermediary units can amplify and relay the transmission without ever needing to decrypt the signal. Thus, the signal remains encrypted from its initial origination point until it reaches its final intended destination.

In a preferred embodiment, the microphone unit in accordance with the present invention will allow the user to manually select between an encrypted transmission, or secure, mode and a non-encrypted, or clear, mode. This allows the user to turn off the secure mode in situations where the user desires to communicate with other radios that are not equipped with the ability to receive secure mode transmissions. In a preferred embodiment, a switch is provided on the side of the microphone unit which allows the microphone unit output to be connected directly to the microphone output, thus bypassing the remaining components in the microphone unit and allowing for clear mode transmissions.

The use of the microphone units in accordance with the present invention provides an efficient, complete security system for an existing radio system. Security is obtained against individuals attempting to eavesdrop on transmissions using scanners and/or lost or stolen radios. All of these features are accomplished through the use of simple and cost-effective microphone units in accordance with the present invention. In light of the ever increasing security concerns present in the world today, the present invention provides a significant improvement to the non-secure systems of the prior art.

It should be understood that the foregoing is illustrative and not limiting and that obvious modifications may be made by those skilled in the art without departing from the spirit of the invention. Accordingly, the specification is intended to cover such alternatives, modifications, and equivalence as may be included within the spirit and scope of the invention as defined in the following claims.
